9 ABSTRACT (Continue on reverse if necessary and identify by block number) This report presents the results of an extensive experimental investigation of the in-line and transverse forces acting on smooth, sand-roughened, and marine-roughened circular cylinders ($k/D = 1/50$) of identical length-to-diameter ratio ($L/D = 2$) placed in a sinusoidally oscillating flow. The drag, inertia, and the maximum force coefficients have been determined through the use of the Fourier analysis. The transverse force (lift) has been analysed in terms of its root-mean-square value. In addition, the amplitude of the first ten harmonics have been determined. The results are presented in both graphical and tabulated form in terms of the Reynolds number, Keulegan-Carpenter number, relative roughness and the frequency parameter β ($= Re/K$).

SUMMARY

This report presents the results of an extensive experimental investigation of the in-line and transverse forces acting on smooth, sand-roughened, and marine-roughened circular cylinders ($k/D = 1/50$) of identical length-to-diameter ratio ($L/D = 2$) placed in a sinusoidally oscillating flow. The drag, inertia, and the maximum force coefficients have been determined through the use of the Fourier analysis. The transverse force (lift) has been analysed in terms of its root-mean-square value. In addition, the amplitude of the first ten harmonics have been determined.

The results have shown that:

1. The smooth-cylinder data presented herein agree quite well with those presented by Sarpkaya [1,2] in 1976 and by Rodenbusch and Gutierrez [7] in 1983;

2. Bearman et al.'s [11] drag coefficients are somewhat lower in the range of comparison (i.e., for $K < 20$) than those of Rodenbusch and Gutierrez [7];

3. The drag, inertia, and the maximum force coefficients for smooth cylinders are at best a very weak function of the Reynolds number (Re) for Re larger than about 100,000;

4. The rms value of the lift coefficient for smooth cylinders reaches a peak value of about 1.6. For Keulegan-Carpenter numbers (K) larger than about 13, the dependence of C_{Lrms} on β ($= Re/K$) decreases rapidly with increasing β ;

5. The analysis of the amplitude of the first ten harmonics of the lift force for smooth cylinders has shown that all harmonics are present, to varying degrees of importance, in the lift force. However, the second and fourth harmonics dominate the drag-inertia dominated regime. The amplitude of all harmonics, with the exception of the second and the fourth, decreases rapidly with increasing β ;

6. For rough cylinders ($k/D = 1/50$), the drag and inertia coefficients become independent of β or of the Reynolds number for β larger than about 4000;

7. The drag coefficient exhibits pronounced secondary peaks in the neighborhood of $K = 17, 24$, and 32. These are directly related to the harmonics of the lift force;

8. The rough-cylinder data presented herein agree quite well with those reported by Sarpkaya [2] in 1976 and show that the effect of roughness, particularly on the drag coefficient, is indeed very profound. The rough-cylinder drag-coefficient

data of Rodenbusch and Gutierrez [7] are somewhat lower than those obtained in the present investigation. Their inertia coefficients for $K > 12$ are somewhat larger. The reasons for these differences are not clear. However, the facts, presented herein show that they are not attributable either to the differences in β or to the blockage effects in the U-tunnel;

9. The maximum force coefficient does not depend on either the relative roughness or β for $K < 7$;

10. The rms value of the lift coefficient reaches a peak value of about 1.8 and is practically independent of β . The secondary oscillations in the rms value of the lift coefficient occur at $K \approx 17, 24, 32$, and 41. These are the same K values at which similar oscillations with relatively smaller amplitudes occur in the drag coefficient;

11. The analysis of the harmonics of the lift force for rough cylinders shows that all harmonics, with the exception of the second, are of the same order of magnitude. In the drag-inertia dominated regime, primarily the second harmonic and to a lesser but equal extent the first, third, and fourth harmonics dominate the lift. The third and fifth harmonics in the neighborhood of $K = 17$; the fourth, sixth, and eighth harmonics in the vicinity of $K = 24$; and the fifth and seventh harmonics in the neighborhood of $K = 32$ dominate the lift force.

12. The use of relatively short test cylinders with identical length-to-diameter ratio ($L/D = 2$) brought into sharper focus the variation of all force coefficients and effectively removed the ambiguities associated with the use of test cylinders with different L/D ratios.

ACKNOWLEDGEMENTS

The work described in this report represents part of a research program supported by the **National Science Foundation** under Agreement No. CEE-8210246. This support is gratefully acknowledged.

A special note of thanks is extended to Mr Jack Mc Kay for his most skilful and dedicated work in the design, construction and smooth operation of the test facilities.

I. INTRODUCTION

In 1976, Sarpkaya [1,2]^T reported the results of a comprehensive series of experiments with a sinusoidally oscillating planar flow about smooth and rough cylinders and introduced the parameter β ($= Re/K = D^2/\nu T$) into the analysis of separated time-dependent flows^{*}. His data and his re-analysis of the Keulegan-Carpenter data, through the use of β , demonstrated clearly the dependence of the force-transfer coefficients (lift, drag and inertia) on the Reynolds number, Keulegan-Carpenter number, and the relative roughness. During the past ten years, these data have stimulated a great deal of research activity and gave rise to a number of questions: Are these data applicable to the design of offshore structures; what is the effect of the orbital motion of the fluid particles; do the data apply to horizontal cylinders; why are the drag coefficients for rough cylinders so large; are there blockage effects; do the in-line and transverse forces vary significantly from cycle to cycle; what is the effect of the spanwise coherence; does Morison's equation hold true for all values of K ($= 2\pi A/D = U_m T/D$), (first introduced by Schlichting [3] in 1932) and Re ($= U_m D/\nu$); why is the added mass coefficient sometimes negative; what happens at very low K values, etc.? These

^T A complete list of references is given on page 47.

^{*} β has been used previously in connection with the analysis of unseparated oscillating flows (see e.g., [3]).

questions were in general valid and required a great deal of additional research for their clarification and resolution (see Sarpkaya and Isaacson [4] for additional details).

A number of projects have been undertaken, both in the laboratory and the field, since 1976. A large scale experiment (Ocean Test Structure experiments, referred to hereafter as the OTS tests) was undertaken by Exxon Production Research Company to evaluate the then present (1979) wave force calculation procedures for fixed, space-frame structures [5]. The Reynolds numbers and Keulegan-Carpenter numbers encountered in the OTS tests were somewhat less than those used in extreme wave design. As with all field experiments, the environmental conditions (wave and current kinematics) could not be specified with great precision for the OTS tests so that some conditions of interest were not observed. The force coefficients exhibited large scatter particularly for $K < 20$. The scatter decreased considerably in the range $20 < K < 45$. The drag coefficients were significantly larger than those previously observed in the field, especially for barnacle-covered cylinders. Heideman, Olsen, and Johansson [5] attributed the scatter in the drag and inertia coefficients to random wake encounters with the current meters. They have concluded that Morison's equation with constant coefficients can be made to fit measured local forces and kinematics satisfactorily over individual half wave cycles and that most of the scatter in the drag coefficient can be explained by the random-wake-encounter concept. Another major

field investigation is that conducted at the Christchurch Bay (CB) by the National Maritime Institute of England. The wave force data obtained from the CB tower have been analyzed by Bishop [6] through the use of a mean-square method.

For the depth station nearest to the sea surface, Bishop found: $C_m = 1.8$ and $C_d = 0.66$ for $K > 30$, increasing C_d and C_m with decreasing K in the range $5 < K < 30$, and $C_m = 2$ for $K < 5$. Bishop noted that C_d and C_m exhibited considerable variation in the range $5 < K < 15$. The reasons offered for this variation were: (i) even the shortest averaging period (40 seconds) was long enough to average out the variations of the force coefficients caused by vortex shedding and wake return, and (ii) the effect of the tidal current acting in conjunction with the vortex shedding in the mid K range. Bishop attributed the low variability of the force coefficients at high K values as a proof of the validity of a simple superposition of the current component to the wave particle velocity.

The CB tower study has demonstrated once again, like the great many other ocean-based experiments before it, that it is possible to obtain force coefficients which will be valuable for the design of structures but it would not be possible to isolate and interpret the significance of various major parameters on the force coefficients. Clearly, it is necessary to treat the two types of studies (laboratory and ocean) with respect to their ultimate objectives. The laboratory experiments are for the purpose of understanding the underlying

mechanisms, whereas the ocean experiments are utilitarian in character and the force coefficients derived from them reflect the combined effect of all the influences including the shortcomings of the speculative generalizations of the MOJS equation.

In 1983, Rodenbusch and Gutierrez [7] reported the results of a joint industry study, carried out in the Maritime Dynamics Laboratory of the Swedish Maritime Research Center (SSPA). A circular cylinder of 1 meter nominal diameter and 3 m long was subjected to various types of forced oscillations in a large basin. A circular plate 5 m in diameter was attached to the top of the test cylinder to promote two-dimensional flow about the cylinder by reducing the effect of the free-surface disturbances. The plate served this purpose quite well at low speeds. But "at speeds above 2 m/s, the flow over the top of the plate produced a drop in the water level near the trailing edge so that the water flowing out from under the plate produced a noticeable stern wave" [8,9]. Forces acting on the central 1 m section were used to deduce the force-transfer coefficients. For rough cylinder tests, the surface was covered uniformly with approximately 6000 roughness elements. The individual roughness elements were right conical frusta of 2 cm height ($k/D = 0.02$) with 1.5 cm top diameter and 3 cm bottom diameter. The roughnesses were located on 4 cm centers in horizontal rows, with each row offset by 2 cm and separated by 3.5 cm. The cylinder diameter was assumed to be 1.04 m, i.e.,

$[D(\text{rough}) = D(\text{smooth}) + 2k]$ in the calculation of the force coefficients through the use of Morison's equation. The force coefficients obtained in the SSPA tests, with planar sinusoidal motion of the cylinder, were compared by Sarpkaya [10] with those obtained in a sinusoidally oscillating flow about smooth and rough cylinders [1,2]. Rodenbusch and Källström [8] and Rodenbusch [9] presented the data obtained in simulated random two-dimensional flows and described a model for the calculation of wave loads on pile template offshore platforms in random directional waves.

In 1985, Bearman, Chaplin, Graham, Kostense, Hall, and Klopman [11] described the results obtained from the measurement of in-line and transverse forces on a small element of a vertical and horizontal cylinder in waves at Keulegan-Carpenter numbers up to 20 and Reynolds numbers up to 5×10^5 . The drag and inertia coefficients showed no obvious dependence on Re and β in the range $4 < K < 20$, $1.46 \times 10^5 < Re < 5.05 \times 10^5$, $2 \times 10^4 < \beta < 5.49 \times 10^4$, and $0.11 < e < 0.65$ where the ellipticity e is defined as the ratio of **rms** vertical velocity to **rms** horizontal velocity.

A number of other investigations either with oscillating cylinders in an initially still water or with stationary cylinders in wave flumes have been conducted. A critical discussion of these is presented by Hogben, Miller, Searle, and Ward [12], Sarpkaya and Isaacson [4], Sarpkaya and Collins [13], Lin and Nath [14] and by Sarpkaya [10,16,17] and will not be repeated here for sake of brevity.

The degree of spanwise correlation of the wave forces on slender structures has been of special concern for a number of reasons: the interpretation of the data obtained from the measurement of **total** forces (vice sectional forces), the understanding of the reasons for the stochastic behavior of the transverse force, the determination of the hydroelastic response of risers, cables, etc.

In the studies cited above, the length-to-diameter ratio (L/D) of the force-sensing element was as follows:

Table 1. Some Details of Related Investigations.

<u>Experiment</u>	<u>Type of motion</u>	<u>L/D</u>
Sarpkaya [1,2]	Planar sinusoidal	5.55-18

Bearman et al. [11]	Laboratory waves	0.5
Present study	Planar sinusoidal	2

Tørum and Reed [18] studied the spanwise correlation of transverse forces at different elevations on a pile due to waves in a model basin. The results have shown that the transverse force is very irregular at a given elevation and that at any probability level, the force peak distribution of different combinations of individual force histories yields a force smaller than the sum of the individual force distributions,

i.e., there are significant amplitude and phase modulations in velocity and pressure along the cylinder. This is in part due to variations in both the strength and frequency of vortex segments along the cylinder and in part due to the phase shifts between various sections along the vortex, separated by a correlation length (the equivalent length over which the velocity fluctuations at similar points in the wake may be described as perfectly correlated).

II. OSCILLATING FLOW SYSTEM

A. U-SHAPED WATER TUNNEL AND ITS EVOLUTION

A U-shaped water tunnel is used to study the time-dependent resistance on various types of bluff bodies. The tunnel consists of thirteen modules to facilitate construction, transportation and assembly. Each module is made of 3/8 inch aluminum plates which are reinforced with 1/2 in. x 4 in. x 22 in. aluminum flanges welded to the plates. The modules were assembled using an air drying silicon-rubber seal between the module frames. The flanges were held together with one inch steel bolts spaced six inches apart. The interior of each module was precision machined so that the largest misalignment was approximately 0.04 inches. Figure 1 is a sketch showing the front view of the tunnel exterior.

The inside cross-section of the two vertical tunnel legs is 6 ft x 3 ft. and that of the horizontal section is 4.67 ft x 3 ft. The size of these areas is dictated by such conditions

as the available ceiling height, pressures to be encountered, amplitude and period of the oscillations, desired range of Reynolds and Keulegan-Carpenter numbers, boundary layer thickness on the walls, etc.

A sketch of the tunnel interior is shown in Fig. 2. The length of the horizontal test section was made twice as large as the maximum amplitude to ensure fully developed uniform flow at the test section. The corners of the tunnel are streamlined to prevent flow separation.

The ancillary equipment for the tunnel consists of plumbing for filling and draining the tunnel with hot and cold water (50° to 160°F), a heat exchanger and an air supply system.

The tunnel was put in operation on **4 July 1975** in essentially the form as described above with the following exceptions. The dimensions of the horizontal section originally were 3 ft. by 3 ft. The oscillations were created by closing a butterfly valve system (mounted on top of one of the legs of the tunnel) and creating a differential water level between the two legs by introducing sufficient amounts of air (at about 50 psi) into the closed chamber and then releasing it quickly by opening the butterfly valves. This action set the fluid in the tunnel in oscillatory motion with a natural period of $T = 5.272$ seconds. The damping of the motion was such that the amplitude of oscillation decreased about 0.13 inches per cycle for the largest amplitude and about 0.06 inches per cycle for amplitudes smaller than about half the maximum. This system worked

well for a number of reasons. First, over a period of 4 complete cycles of oscillation at any mean amplitude, the velocity at the test section changed only about 1%. Secondly, the amplitude, velocity, and acceleration signals were absolutely free from noise and required no filter.

Subsequently, the work on the hydroelastic oscillations of cylinders in sinusoidal flow demonstrated the need for a device which will restore the energy lost due to damping of the motion. Furthermore, it was decided to increase the size of the test section to minimize possible blockage effects.

In **July 1978**, the dimensions of the test section were changed to **4.67 ft by 3 ft** by cutting horizontally the vertical walls of the 35 ft section (see Fig. 2) and welding to them two 20-inch high vertical plates. The corners were again streamlined and the tunnel was provided with large windows for easy access and flow visualization. Furthermore, a new air system was designed and constructed to maintain the amplitude of oscillation constant at a prescribed level as long as desired.

Figure 3 shows the layout of the air supply system. A three horsepower motor drives a centrifugal fan and supplies air to the tunnel. The air from the fan passes through an air control box and into a duct. The control box has two gate valves, one at the box entrance and one on top of the box. The entrance valve is raised and lowered vertically by a threaded rod attached to a manually operated gear and allows for a fine adjustment of the air flow. The top valve is opened and closed

by sliding the hatch horizontally and provides a coarse adjustment of the air flow.

The air then flows through the vertical duct to the three-way valve. The control valve permits the air to flow into the tunnel at prescribed time intervals. Figure 4 shows the details of the three-way control valve. The valve body is a drum which is two feet in diameter and four feet long. Four openings were cut into the drum as shown in Fig. 4. The vane inside the drum is used to direct the motion of the air to-and-from the tunnel. The vane rocks about a mean position by means of a connecting rod through a sprocket wheel and chain mechanism (see Fig. 3). The chain is driven by a variable speed motor and gear. The speed of the motor is controlled by an electronic feed-back control system. It increases or decreases the speed of the motor so as to maintain the period of oscillation within ± 0.001 second about the natural period of the fluid in the tunnel. To insure smooth and uniform rotation of the system, one flywheel is attached to the drive shaft of the connecting rod and another flywheel is attached to the motor drive shaft. Air flows from the duct into the entrance port (marked A in Fig. 4) and is directed by the vane into the tunnel (port B) or to the atmosphere (port D). The vane also provides a smooth flow path for the air escaping from the tunnel (port C) when the supply air is vented to the atmosphere. The plastic flap which rides on the vane further streamlines the path of the escaping air out of the port C.

To oscillate the fluid in the tunnel, the three-way control-valve motor is activated and the centrifugal fan is turned on. The vane rocks back and forth (at a period of $T = 5.3512 \pm 0.0010$ seconds, where 5.3512 seconds is the natural period of the tunnel for the amount of water admitted into the tunnel), supplying the air to the tunnel and then exhausting it to the atmosphere. The amplitude is controlled by the amount of air supplied to the tunnel by opening or closing the gate valves on the control box. The amplitude, once set, remains constant as long as desired with a maximum variation of less than 0.2% per setting over at least 1000 cycles of oscillation. The small variation is primarily due to the voltage fluctuations at the generating plant.

B. FORCE MEASUREMENTS

Depending on the type of bluff body and its arrangement, one or two force transducers (shear gages) are used to measure the instantaneous force. The force transducers can measure both the in-line and transverse forces. The force transducer element is manufactured by BLH Electronics, Inc., under the trade name of LBP-1. There are a number of these gages which can offer a variety of load capacities. One typical gage has a 50 pound capacity with an overload capacity of 200 percent. With a 50 pound load, the gage deflection is about 0.01 inches.

The bellows which protects the strain gages is water-proofed by filling the bellows with liquid silicon without

bringing the rubber into contact with air during the filling operation. Then the ends of the bellows are sealed air tight with clamps. The silicon rubber remains in its liquid form and protects the gages when they are subjected to approximately 20 feet of water pressure at temperatures ranging from 50° to 160° F.

The transducer element is mounted on aluminum pedestal blocks. This assembly is then placed inside a gage housing located on the side of the tunnel (see Fig. 5). The probe end of the pedestal block is inserted into a self-aligning bearing located on the end of the bluff body, for example a circular cylinder.

Gage calibration is accomplished by hanging loads from the test body after rotating the gages to sense only a vertical force. Directional sensitivity of the gages was carefully checked by applying upward loads on the test body through the use of a simple pulley system. Following the calibrations in air, the tunnel is filled with hot water (150° F) and the calibration of the gages is checked once again using the buoyant force acting on the water-tight test body (the buoyant force is both calculated and measured precisely prior to the installation of the test body in the tunnel). Repeated calibrations in air as well as in hot water (at various temperatures) have shown that the gages are linear up to the rated load capacity, produce exactly the same signal for upward and downward loads in air and in hot water (under 20 ft water pressure), and can

sense loads as small as 0.02 pounds with proper amplification of the signal. The cross talk between the vertical and side loads is found to be less than 0.2 percent.

The natural frequency of vibration for the gage housing and bluff body assembly is very high, on the order of 100 Hertz. This is much higher than the largest vortex shedding frequency encountered during the experiments.

C. ACCELERATION, ELEVATION, AND VELOCITY MEASUREMENTS

During the past ten years, various methods have been used to determine the characteristics of the ambient flow at the test section. These consisted of (i) the visual observation and recording of the maximum and minimum water levels in both legs of the tunnel; (ii) the use of calibrated platinum capacitance wires in both legs of the tunnel; (iii) the measurement of the instantaneous acceleration by means of a differential-pressure transducer (see [1,2] for additional details) connected to two pressure taps on the legs of the tunnel; (iv) the measurement of the path of neutrally buoyant particles through the use of motion picture films; (v) measurement of the path of a few particles falling in the Stokes regime again through the use of motion picture films; and (vi) the measurement of the velocity in the test section through the use of an LDV system at selected amplitudes of flow oscillation. These methods yielded the ambient flow acceleration, velocity, and displacement with an error less than 0.05%. The signals generated by

the capacitance wires and differential pressure transducers were entirely free from noise and were never filtered.

D. DATA ACQUISITION SYSTEM

The actual electronic circuitry will vary from one experiment to another depending upon the type of bluff body tested and the type of conditions to which the body is subjected. The following circuits are described for a typical circular cylinder experiment.

The outputs of the two force transducers are amplified by carrier and low-gain amplifiers and then sent to a multichannel recorder for simultaneous analog recording and to a computer system via an A/D converter for analysis and magnetic recording of the digitized data.

The signal sampling rate was chosen to be 720 samples per cycle per channel (i.e., about 135 samples/second/channel or a sample for every 0.5 degrees). The data were recorded for 50 cycles of flow oscillation for each specific experiment and stored on floppy disks and analyzed partly during the experiments (for a quick look) and partly after the experiments (for more detailed analysis of the data).

E. CIRCULAR CYLINDERS

Four circular cylinders with diameters of 4.5, 5.5, 6.5, and 7.5 inches were tested. Each cylinder was made of three pieces: two fixed dummy ends and one active central piece with

$L/D = 2$ (see Fig. 6). A spacing of approximately $1/32$ in. was maintained between the active and dummy pieces. The active segment was mounted concentrically on a supporting cylinder whose ends were in turn connected to two force transducers. The ends of the active cylinder were sealed so that the space between the supporting cylinder and the active segment was kept unflooded. The cylinders were first mirror polished and maintained clean during the smooth cylinder experiments. The cylinder surface was wiped clean at the end of each day in order to prevent the development of water marks on the surface. Subsequently, all three parts of a given cylinder were covered with sieved sand so as to maintain a relative surface roughness of $k/D = 0.02$. The sand was applied on the cylinder surface with an epoxy resin [1,2]. The cylinder diameter was taken to be $D(\text{rough}) = D(\text{smooth}) + 1.2 k = 1.024 D$.

In addition to the foregoing, a marine-roughened cylinder* was also tested (see Fig. 7). It had a clean diameter of 6.125 inches and an apparent diameter of 8 inches. The roughness consisted mainly of rigid excrescences and there were very little or no flexible roughness elements on it. Portions of the roughness were damaged while the pipe was hanging from a temporary platform in the ocean.

The roughness height was measured at as many locations as possible and the relative roughness was found to be approxi-

* The marine-roughened pipe was kindly provided by Dr. John C. Heideman and the Amoco Production Company.

mately $k/D = 1/50$. During most of the experiments the barnacles were alive and uttered a high frequency sound. The intensity of this sound increased when the barnacles were subjected to additional lighting while photographing the pipe. The barnacles remained alive for an additional 48 hours even though the water temperature in the tunnel was raised to about 120 degrees during the first series of tests.

The full 3-ft length of the pipe was used to measure the in-line forces, i.e., $L/D = 3$. The gap between the tunnel wall and one end of the pipe was $1/32$ inch. The pipe was held at a given position relative to the flow direction (called position A). Following a series of experiments, the pipe was rotated 90 degrees (called position B) and the experiments were repeated. The purpose of this decision was to explore the differences in the force coefficients due to the unevenness of the rigid excrescences. In position A, the damaged parts of the roughness were at the bottom of the cylinder (i.e., at the -90 degree position relative to the ambient flow direction). In position B, the damaged section faced the flow and the top and bottom parts of the cylinder were relatively free from damage. Although the entire data obtained with this pipe are reported herein, only those obtained in position B are compared with those obtained with the sand-roughened cylinders.

The following table summarizes the characteristics of all the cylinders used:

Table 2. Characteristics of the Test Cylinders.

III. FORCE COEFFICIENTS AND GOVERNING PARAMETERS

A. IN-LINE FORCE

Data reduction for the forces in-line with the direction of flow oscillation is based on Morison's equation and the Fourier analysis of the force records (sample force traces are shown in Figs. 8-11):

and

$$C_d = -(3/4) \int_0^{2\pi} [F(t) \cos\theta / (\rho U_m^2 D)] d\theta \quad (2)$$

$$C_m = (2K/\pi^3) \int_0^{2\pi} [F(t) \sin\theta / (\rho U_m^2 D)] d\theta \quad (3)$$

in which $F(t)$ represents the fifty-cycle-averaged measured force per unit length; C_d and C_m , the drag and inertia coefficients; and $U(t)$, the velocity of the ambient flow [$U(t) = -U_m \cos\theta$, with $\theta = 2\pi t/T$]. The method of least squares yields identical C_m values and slightly different C_d values.

Two additional coefficients have also been evaluated. These are:

$$C_f(\max) = (\text{Maximum of } F(t) \text{ in a cycle}) / (0.5 \rho D U_m^2) \quad (4)$$

and

$$C_a^2(\text{rms}) = (1/T) \int_0^T F^2(t) dt / (0.5 \rho D U_m^2)^2 \quad (5)$$

B. TRANSVERSE FORCE (LIFT)

The lift force or the transverse force may be normalized in a number of ways (sample force traces are shown in Figs. 12-15). The fact that the lift force is often random in nature (even for bodies subjected to steady flow) has made the use of its **rms** value most desirable. However, it does not give any idea about the frequency about which the transverse force may

be most dominant. It is for this reason that in the present investigation both the rms value and the first ten harmonics of the normalized lift force were calculated from

$$C_L(\text{rms}) = (\text{rms value of the lift force}) / (0.5 \rho D U_m^2) \quad (6)$$

and

$$F_L(t) = (0.5 \rho D U_m^2) \sum_{n=1}^{10} C_L(n) \cos(n\theta - \phi_n) \quad (7)$$

in which $C_L(n)$ is the amplitude of the n -th harmonic and ϕ_n is the phase angle.

The in-line and transverse force coefficients cited above are assumed to be functions of K , k/D , and β (or Re) for the cylinder with $L/D = 2$.

C. REMARKS REGARDING THE DATA

The investigation described herein was designed for the purpose of obtaining data which could serve as reference to all concerned. Thus, no effort has been spared in the acquisition and subsequent analysis of the data. Throughout the investigation, conscious attention has been devoted to the integrity of the experimental procedures, methods of evaluation, and the data reported herein.

The raw data (in-line and transverse force versus time) have been preserved on floppy disks. All test cylinders and their components have also been preserved for future use or retesting.

IV. PRESENTATION AND DISCUSSION OF RESULTS

A. REMARKS

The data are presented in terms of the governing parameters both in graphical and tabulated form (see Appendices). Unless stated, **none of the results have been corrected for tunnel blockage.**

B. SMOOTH CYLINDER DATA

The drag and inertia coefficients for five values of β are shown in Figs. 16-20 (see Appendix A for the tabulated data). It is clear from the perusal of either one of these figures that C_D decreases rapidly as K increases from very small values and reaches a minimum between $K \approx 2$ and $K \approx 3$, depending on the value of β .

Stokes [19] was the first to show that the force acting on a cylinder or sphere oscillating sinusoidally in a viscous fluid is dependent on both K and Re (or β). In the case of a **fixed** circular cylinder in a sinusoidally oscillating flow Stokes force may be expressed in terms of the MOJS equation by noting that over a flow cycle $\cos\theta |\cos\theta|$ may be approximated by $(8/3\pi)\cos\theta$. Then one has (see also Rosenhead [20], p. 392),

$$C_D = (3 \pi^{3/2} K) [(\pi\beta)^{-1/2} + (\pi\beta)^{-1} + O(\pi\beta)^{-3/2}] \quad (8)$$

and

$$C_m = 2 + 4(\pi\beta)^{-1/2} + O(\pi\beta)^{-3/2} \quad (9)$$

Equations (8) and (9) are valid only for large values of β . Wang [21] extended this analysis to $O[(\pi\beta)^{-3/2}]$ using the

method of inner and outer expansions. His solution, valid for $K \ll 1$, $\text{Re}.K \ll 1$, and $\beta \gg 1$, may be reduced to

$$C_d = (3\pi^3/2K) [(\pi\beta)^{-1/2} + (\pi\beta)^{-1} - (1/4)(\pi\beta)^{-3/2}] \quad (10)$$

and

$$C_m = 2 + 4(\pi\beta)^{-1/2} + (\pi\beta)^{-3/2} \quad (11)$$

The expressions (10) and (11) differ from (8) and (9) only in the last terms. Stokes and Wang's solutions yield virtually identical results in the range of their validity, i.e., for large β .

Relatively few experiments have been carried out with sinusoidally oscillating cylinders at low Keulegan-Carpenter numbers. Honji [22] oscillated a circular cylinder in water at rest in the range $70 < \beta < 700$ and $0 < K < 4$, and investigated the stability of the flow. He has delineated three regions in the (K, β) -plane: a region (corresponding to relatively small K) in which no streaks formed because the flow remained attached, stable and two-dimensional; a second region in which the flow became unstable to axially periodic vortices; and a third region in which no clear streaks formed because the flow became turbulent.

Subsequently, Hall [23] carried out a stability analysis of that flow, valid only in the limit $\beta \rightarrow \infty$ and $K \rightarrow 0$, and showed that 'oscillatory viscous flows interacting with rigid boundaries of convex curvature can become unstable to Taylor-Görtler vortices'. His analysis confirmed Honji's data.

Hall's critical Keulegan-Carpenter number may be written as

$$K_{Cr} = Re_{Cr}/\beta = 5.778\beta^{-1/4}(1 + 0.205\beta^{-1/4} + \dots) \quad (12)$$

according to which the critical Reynolds number Re_{Cr} increases with increasing β .

Subsequently, Sarpkaya [24] presented in-line force data for one rough and three smooth cylinders over a large range of β (1035 to 5500) and has shown that (i) the theoretical values of the inertia coefficient agree quite well with those obtained experimentally for K smaller than that corresponding to the inception of boundary-layer transition; (ii) the drag coefficient predicted by the Stokes-Wang analysis agrees well with that obtained experimentally for $K < K_{Cr}$ at which the flow becomes unstable (Honji instability); (iii) the critical regime is followed either by separation and transition or by transition and delayed separation. In either case, separation and minimum drag occur almost simultaneously; (iv) roughness precipitates instability and transition to turbulence in the boundary layers. Its net effect is to increase C_d , relative to the Stokes-Wang prediction, and to delay separation.

The purpose of the present study was not a further investigation of the stability of the flow at very low K values. Thus, the experiments were confined to K values larger than about 1. According to Eq. (12), the critical values of K and Re for $\beta = 2300$ are about 0.86 and 1976, respectively. Thus,

the instability and the rapid change in C_D [24] are not evident in Figs. 16-20 for which the lowest K is about 1.0. The comparison of the Stokes-Wang prediction with the present measurements shows that (see Figs. 16-20) the instability has occurred at smaller K values and the drag coefficient jumped to higher values. The delay in separation due to transition in the boundary layer leads to minimum C_D values which occur at slightly larger K values with increasing β (for additional discussion the reader is referred to [24]).

Figures 16-20 also show that the inertia coefficient is slightly large than 2, at least for K smaller than that corresponding to the minimum drag, and nearly identical to that given by Eq. (11). The ideal values of C_m are as follows:

Table 3. Ideal Values of the Inertia Coefficient for Various Values of β for Smooth and Sand-Roughened Cylinders

$\beta = 2300$	$C_m = 2.047$	$\beta = 2412$	$C_m = 2.046$
$= 3435$	$= 2.039$	$= 3598$	$= 2.038$
$= 4720$	$= 2.033$	$= 4924$	$= 2.032$
$= 6555$	$= 2.028$	$= 6836$	$= 2.027$
$= 11525$	$= 2.020$	$= 9354$	$= 2.023$
		$= 14200$	$= 2.019$

These may be compared with the tabulated data (Appendices A & D) to see that the measured and calculated values of C_m agree fairly well in the range of K values noted above.

In the range of K values between approximately 3 and 12, C_D increases and C_m decreases as the effects of flow separation and vortex shedding become increasingly important, eventually

leading to a very interesting half Karman vortex street in the transverse direction in the range $8 < K < 13$ (Bearman [25], Sarpkaya [10, 26], Williamson [27]). Subsequently, C_m increases, rapidly at first and then slowly, and C_d decreases with increasing K .

The drag and inertia coefficients are compared in Figs. 21 and 22 for $\beta = 6555$ and $\beta = 11525$. It is noted from Fig. 21, as well as from Figs. 16-20, that C_d does not depend (within the range of the experimental errors) on β for $\beta > 2300$ and K smaller than about 1.5. The dependence of boundary-layer transition and separation on K becomes evident for K larger than about 1.5. For K larger than about 3, larger values of β yield smaller C_d and larger C_m values. The dip in C_m in the range $10 < K < 15$ becomes less and less significant as β increases (e.g., $C_m = 0.5$ at $K = 14$ for $\beta = 2300$ and $C_m = 1.4$ at $K = 11$ for $\beta = 11525$). This behavior of the inertia coefficient for smooth cylinders is opposite to that for the rough cylinders, as will be shown later.

For $K > 15$, the two values of β (corresponding to $Re = 98,300$ and $172,875$, both for $K = 15$) yield nearly identical C_d values. This does not mean that C_d becomes independent of Re for all values of Re . It simply means that C_d becomes nearly insensitive to changes in Re in the range of Re values from $6555.K$ to $11525.K$ for $K > 15$ for the data shown in Fig. 21. Similar observations may be made regarding C_m on the basis of Fig. 22.

Figure 23 shows, for $K = 20$, a comparison of the data obtained in 1976 by Sarpkaya [1,2] with those deduced from Figs. 16-20. The agreement between the two sets of data is quite good. The present values of C_D are slightly larger than the previous ones. This is attributed to the better correlation of the flow along the shorter length ($L = 2.D$) of the present test cylinders. Similar comparisons may be made by the reader at other K values using the tabulated data reported in 1976 [1] and in the present investigation.

Figures 24 and 25 show the drag and inertia coefficients, respectively, for four sets of data (Rodenbusch and Gutierrez [7], Sarpkaya [1,2], Bearman et al. [11], and the present data). The following observations may be made: (i) the present data (in the range $10^5 < Re < 4 \times 10^5$) agree reasonably well with those reported by Sarpkaya [1,2] in 1976 and by Rodenbusch & Gutierrez [7] in 1983; (ii) Bearman et al.'s [11] drag coefficients are somewhat lower in the range of comparison (i.e., for $K < 20$) than those of Rodenbusch & Gutierrez. The reasons for this difference are not clear. However, one is tempted to attribute them to the effect of the orbital motion and to the presence of currents in wave channels. Sarpkaya and Storm [28] have shown that the effect of current is to reduce the drag coefficient relative to the no-current case, particularly for $K < 20$; and (iii) the agreement between the present data, Sarpkaya's 1976 data and Rodenbusch & Gutierrez's 1983 data for K larger than about 15 support the view that C_D is at best a

very weak function of Re for Re larger than about 10^5 (in Fig. 24, Re ranges from 10^5 to 18.8×10^5).

Figure 26 shows the present C_{fmax} data as a function of K for all values of β (from 2,300 to 6,555) for the smooth cylinders (see Appendix A for the tabulated data).

For $K < 9$, C_{fmax} is independent of β in the range of β values noted above. For $K > 9$, the maximum in-line force coefficient depends on β as well as on K . However, the dependence of C_{fmax} on β decreases rapidly with increasing β . In other words, for large values of β , C_{fmax} depends only on K within the range of β values encountered in the present investigation.

The **rms** value of the lift coefficient for smooth cylinders is shown in Fig. 27* (see Appendix B for the tabulated data). In the range $2300 < \beta < 11525$, C_{Lrms} reaches a peak value of about 1.6. For K larger than about 13, the dependence of C_{Lrms} on β decreases rapidly with increasing β . The data shown in Fig. 27 are quite similar to those reported in 1976 [1].

The amplitudes of the first five harmonics of the lift force for the smooth cylinders are shown in Figs. 28-31 (see Appendix C for the tabulated data). Clearly, all harmonics are present, to varying degrees of importance, in the lift force. However, the second and fourth harmonics dominate the drag/-inertia dominated regime. The third harmonic is relatively

* The lift data for smooth cylinders were obtained only at $\beta = 2300, 3435, 4720$, and 6555 (i.e., with water at room temperatures only).

strong in the neighborhood of $K = 18$. One additional observation to be made is that the importance of all harmonics, with the exception of the second and the fourth, decreases rapidly with increasing β (see Fig. 31). Thus, the transverse force should be well represented by its second and fourth harmonics in the drag/inertia dominated regime at sufficiently high Reynolds numbers (say Re larger than about 50,000).

C. ROUGH CYLINDER DATA

The drag and inertia coefficients for the sand-roughened cylinders ($k/D = 1/50$) are shown in Figs. 32 through 37 for β from 2412 to 14200 (see Appendix D for the tabulated data). Several facts emerge from these figures. The drag coefficient decreases with K for K smaller than about 2 and then rises to a maximum near $K = 10$. Subsequently, C_d decreases with increasing K within the range of K values encountered. The said decrease in C_d is not smooth and there are several humps or increases and decreases in C_d . The first of these increases occurs at $K \approx 17$, the second at $K \approx 24$, and the third at $K \approx 32$. The amplitude of these secondary oscillations in C_d decreases with increasing K . Repeated experiments have shown that these oscillations are not only real but also are directly related to the harmonics of the lift force. It will be shown later that the first, third, and fifth harmonics at $K \approx 17$, the fourth, sixth, and eighth harmonics at $K \approx 24$, and the fifth, seventh, and ninth harmonics at $K \approx 32$ are very prominent. This

is reflected in the variation of the drag coefficient in the said range of K values.

The inertia coefficient starts out at values slightly larger than 2, then decreases rather rapidly at $K \approx 7$, and then increases, rapidly at first and then gradually. Figures 31-34 also show that C_m decreases with increasing β (from 2412 to 4924) in the range $10 < K < 15$. As noted earlier, this is contrary to the variation of C_m with β for the smooth cylinder.

The dependence on β of the drag and inertia coefficients for the rough cylinders will be discussed through the use of Figs. 38-41. Figure 38 is a combined plot of the drag and inertia coefficients for $\beta = 6836$ and $\beta = 14,200$. The corresponding sets of data (including the magnitude and position of the secondary oscillations in C_d) are nearly coincident.* It is clear that C_d and C_m do not depend on β for the two values of β noted above. In other words, the drag and inertia coefficients in Fig. 38 vary only with K and are independent of the Reynolds number.

One is now in a position to explore the dependence or lack of dependence of the force coefficients on β over a larger range of β .

* This is more remarkable than it may appear at first sight. It is recalled that the experiments at $\beta = 6836$ were carried out in water at room temperature and those at $\beta = 14,200$ in hot water at nearly twice the room temperature. Furthermore, each experiment was repeated twice at different times over a one month period.

Figure 39 shows C_d and C_m for four values of β (4924, 6836, 9354, and 14,200; see Table 2 for the cylinders used). Once again it is noted that the force coefficients do not depend on β in the range of β values noted. The differences between the four sets of data are no more than the scatter in any one set.

Figure 40 shows the entire drag-coefficient data for all values of β (from 2412 to 14,200) for the sand-roughened cylinders. This figure and the tabulated data (see Appendix D) show that C_d values for $\beta = 2412$ are lower than the rest. The C_d values for $\beta = 3598$ are sandwiched between those for $\beta = 2412$ and the rest. One may, therefore, conclude that for rough cylinders ($k/D = 1/50$) the drag coefficient becomes independent of β or of the Reynolds number for β larger than about 4,000 (± 200). Even though the data at large β were obtained for K smaller than about 40, there is no reason to expect that C_d will become dependent on Re for $K > 40$ as long as the Reynolds number is kept larger than about 4,000. K , for $k/D = 1/50$.

Figure 41 shows the inertia coefficient for all values of β (from 2412 to 14,200). This figure and the tabulated data show that C_m becomes independent of β for β larger than about 4,000. It is also noted that the dependence of the inertia coefficient on β (or on the Reynolds number) for $\beta < 4000$ is relatively weaker than that of the drag coefficient. Furthermore, variations in C_m with β for K larger than about 15 are obscured by the scatter in the data in the drag dominated regime (where the precise value of C_m is not of special concern).

Figures 42 and 43 show, for $K = 20$ and $K = 30$ respectively, the comparison of the drag coefficients obtained in the present investigation with those reported in 1976 by Sarpkaya [2]. For $K = 20$ and $k/D = 1/50$, the two sets of data agree quite well and show that C_D becomes independent of Re for Re larger than about 80,000 (i.e., for $\beta > 4000$). For $K = 30$, the mean of the present data is slightly lower (about 3%) than that reported in 1976. The drag coefficient becomes independent of Re for $Re > 120,000$ (i.e., for $\beta > 4000$). Figures 42 and 43 also show that for smaller relative roughnesses, C_D and C_m become independent of β at larger values of β , i.e., at larger Re for a given K .

Figures 46 and 47 show C_D and C_m for the marine-roughened cylinder (in position A) for various values of β . The relatively large scatter in C_m is attributed to the damage in roughness near the separation region on one side of the cylinder.

Figures 46 and 47 show C_D and C_m for the same cylinder in position B. The scatter in C_m is relatively smaller. The magnitude of C_D in the drag-inertia dominated regime is somewhat larger than that shown in Fig. 44. The said difference is attributed to the orientation of the damaged roughness in the two cases.

Figures 48 and 49 show a comparison of the drag and inertia coefficients for three sets of data: the present sand-roughened cylinder data (for $\beta = 9354$ and $\beta = 14,200$ only, for

sake of clarity); the marine-roughened cylinder data (for the position B); and the rough cylinder data of Rodenbusch and Gutierrez [7], all for $k/D = 1/50$. The sand-roughened and marine-roughened cylinder data agree quite well. Six of the C_d values* of Rodenbusch and Gutierrez are somewhat lower than those obtained in the present investigation. Furthermore, their C_m values for $K > 12$ are somewhat larger. The reasons for these differences are not clear. However, the facts presented herein show that they are not attributable either to the differences in β or to the blockage effects in the U-tunnel. It is tempting to think that the vibrations of the large test cylinder, the condition of the free surface in the test basin, the filtering of the data and the regularity of the shape and distribution of the roughness elements in the SSPA tests [7] may be partly responsible for the said differences[†].

Figure 50 shows C_{fmax} as a function of K for all values of β (from 2412 to 14,200) for the sand-roughened cylinders (see Appendix D for the tabulated data). For $K < 7$, C_{fmax} is inde-

* The six data points are at: $K = 3.14$ for $Re = 440,000$ and $\beta = 140,000$; $K = 6.28$ for $Re = 440,000$ and $\beta = 70,000$; $K = 12.56$ for $Re = 880,000$ and $\beta = 70,000$; $K = 25.12$ for $Re = 1,880,000$ and $\beta = 75,000$; $K = 31.4$ for $Re = 880,000$ and $\beta = 28,000$; and $K = 31.4$ for $Re = 1,750,000$ and $\beta = 56,000$.

[†] The increase of $D(\text{smooth})$ by $2k$ in [7] rather than by $1.2k$ (as in the present study) in calculating $D(\text{rough})$ lowers C_d by only 2% and thus cannot account for the differences noted above.

pendent of β in the range of β values noted above. For $K > 7$, the maximum in-line force coefficient depends on β as well as on K . However, the dependence of C_{fmax} on β is rather weak and decreases rapidly with increasing β . For $\beta > 2412$, it is difficult to make a distinction between a negligible dependence on β and a small scatter in the data.

The C_{fmax} values for a smooth ($\beta = 11,525$) and a sand-roughened cylinder ($\beta = 14,200$) are compared in Fig. 51. This figure and Figs. 26 and 50 show conclusively that (i) the maximum force coefficient does not depend on either the relative roughness or β for $K < 7$; (ii) C_{fmax} for the rough cylinder is considerably larger than that for the smooth cylinder for $K > 7$; and (iii) as noted earlier, C_{fmax} for the smooth cylinder continues to be independent of β up to $K = 9$.

The **rms** value of the lift coefficient for sand-roughened cylinders is shown in Fig. 52* (see Appendix E for the tabulated data). In the range $2412 < \beta < 6836$, C_{Lrms} reaches a peak value of about 1.8 and is practically independent of β (C_{Lrms} for $\beta = 2412$ is slightly lower than the rest). The secondary oscillations in the rms value of the lift coefficient occur at $K \approx 17, 24, 32$, and 41 . These are the same K values at which similar oscillations with relatively smaller amplitudes occur in C_d (see Figs. 32-40).

* The lift data for the sand-roughened cylinders were obtained only at $\beta = 2412, 3598, 4924$, and 6836 (i.e., with water at room temperatures only).

Figure 53 shows a comparison of the C_{Lrms} values of a smooth ($\beta = 6555$) and a rough cylinder ($\beta = 6836$) for nearly identical β values. Clearly, C_{Lrms} for the rough cylinder remains high and its maximum occurs at a lower K relative to the smooth cylinder. The implications of these are that the separation occurs at a smaller angle at a given time relative to that for the smooth cylinder and the vortices are stronger and better correlated.

The amplitude of the first five harmonics of the lift force for the sand-roughened cylinders are shown in Figs. 54-57 (see Appendix F for the tabulated data). Clearly, all harmonics are present, to varying degrees of importance, in the lift force. In the drag-inertia dominated regime, primarily the second harmonic and to a lesser but equal extent the first, third, and fourth harmonics dominate the lift. The third and fifth harmonics in the neighborhood of $K = 17$; the fourth, sixth, and eighth harmonics in the vicinity of $K = 24$; and the fifth and seventh harmonics in the neighborhood of $K = 32$ dominate the lift. What is rather remarkable is that all harmonics, with the exception of the second, are of the same order of magnitude (see also the tabulated data in Appendix F). A comparison of Figs. 54-57 with Figs. 28-31 shows that the effect of roughness is to increase significantly the importance of higher order harmonics in the transverse force. It is suggested that the roughness increases the wall shear, the boundary layer thickness, and the spanwise coherence, decreases the

separation angle, and increases the vorticity flux and hence the strength and the lifespan of the vortices relative to those for the smooth cylinder. The measurement of the vortex strength and the separation angle as a function of time is at best very difficult. The consequences of roughness, as reflected indirectly in the time-invariant in-line and transverse force coefficients, cannot yet be predicted theoretically. The application of the discrete vortex model to oscillating flow about a smooth cylinder will be the subject of another report.

V. CONCLUSIONS

The results presented herein warrant the following conclusions:

1. The smooth-cylinder data presented herein agree quite well with those presented by Sarpkaya [1,2] in 1976 and by Rodenbusch and Gutierrez [7] in 1983;

2. Bearman et al.'s [11] drag coefficients are somewhat lower in the range of comparison (i.e., for $K < 20$) than those of Rodenbusch and Gutierrez [7];

3. The drag, inertia, and the maximum force coefficients for smooth cylinders are at best a very weak function of the Reynolds number (Re) for Re larger than about 100,000;

4. The rms value of the lift coefficient for smooth cylinders reaches a peak value of about 1.6. For Keulegan-Carpenter numbers (K) larger than about 13, the dependence of C_{Lrms} on β ($= Re/K$) decreases rapidly with increasing β ;

5. The analysis of the amplitude of the first ten harmonics of the lift force for smooth cylinders has shown that all harmonics are present, to varying degrees of importance, in the lift force. However, the second and fourth harmonics dominate the drag-inertia dominated regime. The amplitude of all harmonics, with the exception of the second and the fourth, decreases rapidly with increasing β ;

6. For rough cylinders ($k/D = 1/50$), the drag and inertia coefficients become independent of β or of the Reynolds number for β larger than about 4000;

7. The drag coefficient exhibits pronounced secondary peaks in the neighborhood of $K = 17, 24$, and 32 . These are directly related to the harmonics of the lift force;

8. The rough-cylinder data presented herein agree quite well with those reported by Sarpkaya [2] in 1976 and show that the effect of roughness, particularly on the drag coefficient, is indeed very profound. The rough-cylinder drag-coefficient data of Rodenbusch and Gutierrez [7] are somewhat lower than those obtained in the present investigation. Their inertia coefficients for $K > 12$ are somewhat larger. The reasons for these differences are not clear. However, the facts, presented herein show that they are not attributable either to the differences in β or to the blockage effects in the U-tunnel;

9. The maximum force coefficient does not depend on either the relative roughness or β for $K < 7$;

10. The rms value of the lift coefficient reaches a peak value of about 1.8 and is practically independent of β . The secondary oscillations in the rms value of the lift coefficient occur at $K \approx 17, 24, 32$, and 41. These are the same K values at which similar oscillations with relatively smaller amplitudes occur in the drag coefficient;

11. The analysis of the harmonics of the lift force for rough cylinders shows that all harmonics, with the exception of the second, are of the same order of magnitude. In the drag-inertia dominated regime, primarily the second harmonic and to a lesser but equal extent the first, third, and fourth harmonics dominate the lift. The third and fifth harmonics in the neighborhood of $K = 17$; the fourth, sixth, and eighth harmonics in the vicinity of $K = 24$; and the fifth and seventh harmonics in the neighborhood of $K = 32$ dominate the lift force.

12. The use of relatively short test cylinders with identical length-to-diameter ratio ($L/D = 2$) brought into sharper focus the variation of all force coefficients and effectively removed the ambiguities associated with the use of test cylinders with different L/D ratios.

Fig. 53 RMS lift coefficient for a smooth and sand-roughened cylinder,
smooth cylinder: o, $\beta = 6555$; rough cylinder: *, $\beta = 6836$.

Fig. 54 Amplitude of the harmonics of the lift force for a rough cylinder, $\beta = 24^\circ$.

Fig. 55 Amplitude of the harmonics of the lift force for a rough cylinder, $\beta = 3598$.

Fig. 56 Amplitude of the harmonics of the lift force for a rough cylinder, $\beta = 4924$.

Fig. 57 Amplitude of the harmonics of the lift force for a rough cylinder, $\beta = 6836$.
